1. Introduction

Particle swarm optimization (PSO) refers to a large class of heuristic optimization algorithms that use an analogy with animal flocking behavior in order to construct more robust optimization algorithms than many alternatives (Clerc & Kennedy, 2002; Blum & Li, 2008; Clerc, 2010). This robustness makes them attractive for more difficult optimization problems, especially when near optimal solutions are tolerable. We introduce a new class of PSO algorithms, called adaptively tuned PSO (AT-PSO), which exploit an analogy with a class of adaptive Markov chain Monte Carlo algorithms in order to tune a crucial parameter of the PSO algorithm adaptively based on the state of the particle swarm. We show that the resulting algorithms tend to be superior to many PSO alternatives. Additionally, we several PSO algorithms by applying them to choosing a set of new monitoring locations for ozone in Harris County, Texas, where Houston is located. Section 2 introduces various PSO and AT-PSO algorithms, and briefly discusses the results of an extended simulation study comparing them. Section 3 introduces the generic spatial design problem and the Houston area ozone problem as an instance of that problem, and compares several PSO algorithms and some alternatives to solving the problem. Finally, Section 4 discusses our results and concludes.

2. Particle swarm optimization

We briefly describe PSO here; refer to Blum & Li (2008) for a comprehensive introduction, Clerc (2010) for details, and Clerc (2011) for good default versions of the algorithm. Suppose that we wish to minimize some objective function $Q(\boldsymbol{\theta}) : \mathbb{R}^D \rightarrow \mathbb{R}$. Let $i = 1, 2, \dots, n$ index a set of particles over time, $t = 1, 2, \dots, T$, where in every period each particle consists of a location $\boldsymbol{\theta}_i(t) \in \mathbb{R}^D$, a velocity $\mathbf{v}_i(t) \in \mathbb{R}^D$, a personal best location $\mathbf{p}_i(t) \in \mathbb{R}^D$, and a group best location $\mathbf{g}_i(t) \in \mathbb{R}^D$. Here we mean “best” in the sense of minimizing Q , so $Q(\mathbf{p}_i(t)) \geq Q(\boldsymbol{\theta}_i(s))$ for any $t \geq s$. The group best location is defined with respect to some neighborhood \mathcal{N}_i of particle i ; that is,

*Email:

$\mathbf{g}_i(t) = \arg \min_{\{\mathbf{p}_j(t) | j \in \mathcal{N}_i\}} Q(\mathbf{p}_j(t))$. In the simplest case where the entire swarm is the neighborhood of each particle, $\mathbf{g}_i(t) \equiv \mathbf{g}(t) = \arg \min_{\{\mathbf{p}_j(t) | j \in 1:n\}} Q(\mathbf{p}_j(t))$. The generic PSO algorithm updates each particle i as follows:

$$\begin{aligned} \mathbf{v}_i(t+1) &= \omega \mathbf{v}_i(t) + \phi_1 \mathbf{r}_{1i}(t) \circ \{\mathbf{p}_i(t) - \boldsymbol{\theta}_i(t)\} + \phi_2 \mathbf{r}_{2i}(t) \circ \{\mathbf{g}_i(t) - \boldsymbol{\theta}_i(t)\}, \\ \boldsymbol{\theta}_i(t+1) &= \boldsymbol{\theta}_i(t) + \mathbf{v}_i(t+1), \\ \mathbf{p}_i(t+1) &= \begin{cases} \mathbf{p}_i(t) & \text{if } Q(\mathbf{p}_i(t)) \leq Q(\boldsymbol{\theta}_i(t+1)) \\ \boldsymbol{\theta}_i(t+1) & \text{otherwise,} \end{cases} \\ \mathbf{g}_i(t+1) &= \arg \min_{\{\mathbf{p}_j(t+1) | j \in \mathcal{N}_i\}} Q(\mathbf{p}_j(t+1)), \end{aligned} \quad (1)$$

where \circ denotes the Hadamard product (element-wise product), $\mathbf{r}_{1i}(t)$ and $\mathbf{r}_{2i}(t)$ are each vectors of D random variates independently generated from the $U(0, 1)$ distribution, and $\omega > 0$, $\phi_1 > 0$, and $\phi_2 > 0$ are user-defined parameters. The term $\omega \mathbf{v}_i(t)$ controls the particle's tendency to keep moving in the direction it is already going, so ω is called the inertia parameter. Similarly $\phi_1 \mathbf{r}_{1i}(t) \circ \{\mathbf{p}_i(t) - \boldsymbol{\theta}_i(t)\}$ controls the particle's tendency to move towards its personal best location while $\phi_2 \mathbf{r}_{2i}(t) \circ \{\mathbf{g}_i(t) - \boldsymbol{\theta}_i(t)\}$ controls its tendency to move toward its group best location, so ϕ_1 and ϕ_2 are called the cognitive correction factor and social correction factor, respectively (Blum & Li, 2008). This version of PSO is equivalent to Clerc & Kennedy (2002)'s constriction type I particle swarm, though there are many other variants. One default choice sets $\omega = 0.7298$ and $\phi_1 = \phi_2 = 1.496$ (Clerc & Kennedy, 2002) while another sets $\omega = 1/(2 \ln 2) \approx 0.721$ and $\phi_1 = \phi_2 = 1/2 + \ln 2 \approx 1.193$ (Clerc, 2006).

Any PSO variant can also be combined with various neighborhood topologies that control how the particles communicate to each other. The default global topology allows each particle to see each other particle's previous best location for the social components of their respective velocity updates, but this can cause inadequate exploration and premature convergence. Alternative neighborhood topologies limit how many other particles each particle can communicate with. We use a variant of the stochastic star topology (Miranda et al., 2008). Each particle informs itself and k random particles from the swarm, sampled with replacement during initialization of the algorithm. On average this implies that each particle is informed by k particles, though a small number of particles will often be informed by many of the other particles

Bare bones PSO (BBPSO) is a variant of PSO introduced by Kennedy (2003) that strips away the velocity term. Let $\theta_{ij}(t)$ denote the j th coordinate of the position for the i th particle in period t , and similarly for $p_{ij}(t)$ and $g_{ij}(t)$. Then the BBPSO algorithm obtains a new position coordinate θ_{ij} via

$$\theta_{ij}(t+1) \sim N\left(\frac{p_{ij}(t) + g_{ij}(t)}{2}, |p_{ij}(t) - g_{ij}(t)|^2\right). \quad (2)$$

The updates of $\mathbf{p}_i(t)$ and $\mathbf{g}_i(t)$ are the same as in (1). We explain the essential ideas of PSO and BBPSO in this section, though several modifications can be made to improve performance. Appendix A details each of the modifications we use, most of which come from Clerc (2011). In the next two subsections we introduce adaptively-tuned BBPSO and adaptively-tuned PSO respectively. Both of these algorithms can be combined with the various modifications we discuss in Appendix A.

2.1. Adaptively tuned BBPSO

BBPSO adapts the size effective search space of the swarm over time through the variance term, $|p_{ij}(t) - g_{ij}(t)|^2$. As the personal best locations of the swarm move closer together, these variances decrease and the swarm explores locations which are closer to known high value areas in the space. This behavior is desirable, but the adaptation is forced

to occur only through personal and group best locations. In order to allow the algorithm to adapt in a more flexible manner, we modify the BBPSO variance to $\sigma^2(t)|p_{ij}(t) - g_{ij}(t)|^2$ and tune $\sigma^2(t)$ in a manner similar to adaptive random walk Metropolis MCMC algorithms (Andrieu & Thoms, 2008). Define the improvement rate of the swarm in period t as $R(t) = \#\{i : Q(\mathbf{p}_i(t)) > Q(\mathbf{p}_i(t-1))\}/n$ where $\#A$ is the number of members of the set A , and let R^* denote the target improvement rate. Then adaptively tuned BBPSO (AT-BBPSO) updates the swarm's personal best and group best locations as in (1), then updates particle locations as follows:

$$\begin{aligned}\theta_{ij}(t+1) &\sim t_{df} \left(\frac{p_{ij}(t) + g_{ij}(t)}{2}, \sigma^2(t)|p_{ij}(t) - g_{ij}(t)|^2 \right), \\ \log \sigma^2(t+1) &= \log \sigma^2(t) + c \times \{R(t+1) - R^*\},\end{aligned}\tag{3}$$

where df is a user chosen degrees of freedom parameter and c is another user chosen parameter that controls the speed of adaptation. We use a t kernel instead of a Gaussian in order to allow for more flexibility, and we find $df = 1$ appears to combine well with adaptively tuning $\sigma^2(t)$. Setting the target rate from $R^* = 0.3$ to $R^* = 0.5$ tends to yield good AT-BBPSO algorithms, which is unsurprising given the connection to adaptive random walk Metropolis (Gelman et al., 1996). The parameter c controls the speed of adaptation so that larger values of c mean the algorithm adapts $\sigma^2(t)$ faster. We find that $c = 0.1$ works well, though anything within an order of magnitude yields similar results. We use $\sigma^2(0) = 1$ to initialize the algorithm at the standard BBPSO algorithm.

Both using a t kernel and adding a fixed scale parameter have been discussed in the BBPSO literature, but as Kennedy (2003) notes, something about setting $\sigma^2 = 1$ is special that causes the algorithm to work well. A similar BBPSO algorithm from Hsieh & Lee (2010) sets $\sigma^2 < 1$ for an initial set of iterations, then eventually sets $\sigma^2 = 1$. The authors also suggest dynamically adjusting σ^2 in the early stage of the algorithm before they are set to one, but give no suggestion for how to do this. AT-BBPSO is able to adapt its value on the fly based on local knowledge about the objective function. If too much of the swarm is failing to find new personal best locations, AT-BBPSO proposes new locations closer to known high value areas. If too much of the swarm is improving, AT-BBPSO proposes bolder locations in an effort to make larger improvements. This ability to adapt to local information about the objective function allows AT-BBPSO to more quickly traverse the search space towards the global optimum, though by using local information AT-BBPSO does risk premature convergence to a local optimum. The adaptively tuned component of AT-BBPSO can also be combined with most BBPSO variants, some of which are outlined in Appendix A. In Appendix B we conduct a simulation study on several test functions that compares AT-BBPSO variants to other PSO and BBPSO variants in order to justify the parameter settings discussed above and demonstrate AT-BBPSO variants are attractive PSO algorithms.

2.2. Adaptively-tuned PSO

In AT-BBPSO variants, the parameter $\sigma(t)$ partially controls the effective size of the swarm's search area, and we increase or decrease $\sigma(t)$ and consequently the search area depending on how much of the swarm is finding new personal best locations. In standard PSO the inertia parameter, denoted by ω in (1), is roughly analogous to σ^2 in BBPSO. It controls the effective size of the swarm's search area by controlling how the magnitude of the velocities evolve over time. In AT-BBPSO we use an analogy with tuning a random walk Metropolis-Hastings MCMC algorithm in order to build intuition about how to tune $\sigma(t)$. The analogy is much weaker in this case; nonetheless, the same mechanism works well to tune $\omega(t)$. Formally, AT-PSO updates personal and group best locations as in (1) and updates

$\omega(t)$ and particle locations as follows:

$$\begin{aligned} \mathbf{v}_i(t+1) &= \omega(t+1)\mathbf{v}_i(t) + \phi_1 \mathbf{r}_{1i}(t) \circ \{\mathbf{p}_i(t) - \boldsymbol{\theta}_i(t)\} + \phi_2 \mathbf{r}_{2i}(t) \circ \{\mathbf{g}_i(t) - \boldsymbol{\theta}_i(t)\}, \\ \boldsymbol{\theta}_i(t+1) &= \boldsymbol{\theta}_i(t) + \mathbf{v}_i(t+1), \\ \log \omega(t+1) &= \log \omega(t) + c \times \{R(t+1) - R^*\}, \end{aligned} \quad (4)$$

where $R(t)$ is the improvement rate of the swarm in iteration t , R^* is the target improvement rate, and c controls how much $R(t)$ changes on a per iteration basis. Again, we find that target rates from $R^* = 0.3$ to 0.5 work well for AT-PSO. The value of c controls the speed of adaptation. We use $c = 0.1$ as a default value and in simulations (not reported here), we find that the gains from optimizing c appear to be small. The adaptive tuning piece of this algorithm can be combined with almost any PSO variant, and Appendix A describes the various modifications to the standard PSO algorithm we employ, both in conjunction with AT and without it.

The idea of time-varying $\omega(t)$ has been in the PSO literature for some time. An early suggestion was to set $\omega(0) = 0.9$ and deterministically decrease it until it reaches $\omega(T) = 0.4$ after the maximum number of iterations allowed (Eberhart & Shi, 2000). In particular, Tuppandung & Kurutach (2011) suggest defining $\omega(t)$ via the parameterized inertia weight function $\omega(t) = \frac{1}{1 + (\frac{t}{\alpha})^\beta}$ where α and β are user-defined parameters. Roughly, α controls how low $\omega(t)$ can go and β controls how fast it gets there, so α and β can be thought of as intercept and slope parameters respectively. The suggestion in Tuppandung & Kurutach (2011) is to set α to a small fraction of the total amount of iterations in which the algorithm is allowed to run (e.g., 10% or 20%), and set β between one and four. We call this type of PSO algorithm deterministic inertia PSO (DI-PSO).

DI-PSO tends to improve on standard PSO if $\omega(t)$'s progression is set appropriately, but this can be difficult and often depends on the problem. A priori it may not be clear exactly which approach is best for any given problem, so an automatic method is desirable. A major strength of AT-PSO relative to DI-PSO and standard PSO is that AT-PSO can increase $\omega(t)$ when information from the swarm suggests there is an unexplored high value region of the space. Just like in AT-BBPSO, this mechanism provides a way for the swarm to adapt its behavior on the fly based on local conditions and speed up convergence by allowing the particles that do improve to make larger improvements, but it can also cause premature convergence to a local optimum. While DI-PSO monotonically decreases $\omega(t)$ toward some minimum value, AT-PSO typically oscillates $\omega(t)$ so that the algorithm alternates between exploring and exploiting more, relative to standard PSO. Appendix B contains an extended simulation study comparing a variety of these PSO and BBPSO algorithms on a suite of test functions that demonstrates some of the behavior detailed above and shows that AT-PSO is an attractive PSO algorithm.

Another similar algorithm comes from Zhang et al. (2003). In their algorithm, ω is constant while ϕ_1 and ϕ_2 not only vary across time, but also across the swarm. Then each particle adapts its values of ϕ_1 and ϕ_2 based on how much it improves on its personal best location. The key difference is that the adaptation is local to each specific particle while in AT-PSO the adaptation is global. AT-PSO takes into account less information by ignoring local conditions of the particles, but the adaptation scheme is simpler.

3. The Spatial Design Problem

Suppose we are interested predicting some spatially indexed response variable $Y(\mathbf{u})$, $\mathbf{u} \in \mathcal{D} \subseteq \mathbb{R}^2$ at a set of target locations $\mathbf{t}_1, \mathbf{t}_2, \dots, \mathbf{t}_{N_t} \in \mathcal{D}$. Let $\mathbf{s}_1, \mathbf{s}_2, \dots, \mathbf{s}_{N_s} \in \mathcal{D}$ denote a set of N_s fixed sampling locations within the spatial domain. The design problem is to add N_d new sampling locations in order to optimize the amount we learn about $Y(\mathbf{u})$ at the target locations. Let $\mathbf{d}_1, \mathbf{d}_2, \dots, \mathbf{d}_{N_d} \in \mathcal{D}$ denote a set of candidate design points and suppose that $Y(\mathbf{u})$

is a geostatistical process with mean function $\mu(\mathbf{u}) = \mathbf{x}(\mathbf{u})'\boldsymbol{\beta}$ for some covariate $\mathbf{x}(\mathbf{u})$ known at every point in \mathcal{D} and some covariance function $C(\mathbf{u}, \mathbf{v})$ for $\mathbf{u}, \mathbf{v} \in \mathcal{D}$. Not all covariates can be known a priori at every point in the spatial domain; however, covariates that are known functions of the location satisfy this constraint. Once the design points are selected, we observe $Z(\mathbf{d}_i)$ for $i = 1, 2, \dots, N_d$ and $Z(\mathbf{s}_i)$ for $i = 1, 2, \dots, N_s$ where $Z(\mathbf{u}) = Y(\mathbf{u}) + \varepsilon(\mathbf{u})$ and $\varepsilon(\mathbf{u})$ is mean zero white noise with variance τ^2 , representing measurement error. Typically $\boldsymbol{\beta}$, τ^2 , and $C(\cdot, \cdot)$ are unknown and must be estimated, though for now we will treat them as known.

To completely specify the problem we need to define an informative design criterion. Intuitively, the larger the mean square prediction error (MSPE), i.e. the kriging variance, is at each of the target locations, the less information we have about $Y(\mathbf{u})$ at those locations. A common design criterion is to optimize function of these variances, e.g. to minimize the mean kriging variance or the maximum kriging variance over all target locations. These criteria are somewhat naive since they ignore parameter uncertainty, and taking that into account will often change the optimal design (Zimmerman, 2006).

3.1. Universal Kriging

In universal kriging, $C(\cdot, \cdot)$ and τ^2 are treated as known while $\boldsymbol{\beta}$ is treated as a parameter that needs to be estimated. Let \mathbf{Z} be the vector of $Z(\mathbf{s}_i)$ s and $Z(\mathbf{d}_i)$ s, \mathbf{X} denote the corresponding stacked $\mathbf{x}(\mathbf{s}_i)$'s and $\mathbf{x}(\mathbf{d}_i)$'s, $\mathbf{C}_Z = \text{cov}(\mathbf{Z})$ where $\text{cov}[Z(\mathbf{u}), Z(\mathbf{v})] = C(\mathbf{u}, \mathbf{v}) + \sigma_\varepsilon^2 \mathbf{1}(\mathbf{u} = \mathbf{v})$, and $\mathbf{c}_Y(\mathbf{t}_i) = \text{cov}[Y(\mathbf{t}_i), \mathbf{Z}]$ where $\text{cov}[Y(\mathbf{t}_i), Z(\mathbf{u})] = C(\mathbf{t}_i, \mathbf{u})$. The universal kriging predictor of $Y(\mathbf{t}_i)$ is $\hat{Y}_{uk}(\mathbf{t}_i; \mathbf{d}) = \mathbf{x}(\mathbf{t}_i)'\hat{\boldsymbol{\beta}}_{gls} + \mathbf{c}_Y(\mathbf{t}_i)'\mathbf{C}_Z^{-1}(\mathbf{Z} - \mathbf{X}\hat{\boldsymbol{\beta}}_{gls})$ and the MSPE of $\hat{Y}_{uk}(\mathbf{t}_i)$ is

$$\sigma_{uk}^2(\mathbf{t}_i; \mathbf{d}) = C(\mathbf{t}_i, \mathbf{t}_i) - \mathbf{c}_Y(\mathbf{t}_i)'\mathbf{C}_Z^{-1}\mathbf{c}_Y(\mathbf{t}_i) + [\mathbf{x}(\mathbf{t}_i) - \mathbf{X}'\mathbf{C}_Z^{-1}\mathbf{c}_Y(\mathbf{t}_i)]'[\mathbf{X}'\mathbf{C}_Z^{-1}\mathbf{X}]^{-1}[\mathbf{x}(\mathbf{t}_i) - \mathbf{X}'\mathbf{C}_Z^{-1}\mathbf{c}_Y(\mathbf{t}_i)].$$

where $\hat{\boldsymbol{\beta}}_{gls} = [\mathbf{X}'\mathbf{C}_Z^{-1}\mathbf{X}]^{-1}\mathbf{X}'\mathbf{C}_Z^{-1}\mathbf{Z}$ is the generalized least squares estimate of $\boldsymbol{\beta}$ (Cressie & Wikle, 2011, Section 4.1.2). To avoid clutter we drop the explicit dependence on \mathbf{d} in these equations, but $\mathbf{c}_Y(\mathbf{t}_i)$, \mathbf{C}_Z , \mathbf{Z} , \mathbf{X} , and $\hat{\boldsymbol{\beta}}_{gls}$ all depend on \mathbf{d} . The mean universal kriging variance is given by $\bar{Q}_{uk}(\mathbf{d}) = \frac{1}{N_t} \sum_i^{N_t} \sigma_{uk}^2(\mathbf{t}_i; \mathbf{d})$ while the maximum universal kriging variance is given by $Q_{uk}^*(\mathbf{d}) = \max_{i=1,2,\dots,N_t} \sigma_{uk}^2(\mathbf{t}_i; \mathbf{d})$. Zimmerman (2006) finds that the optimal design under both criteria is highly dependent on the class of mean function of the geostatistical process. In practice we are often interested in predicting at the entire spatial domain rather than a finite set of target locations. This changes the mean and maximum kriging variances to $\bar{Q}_{uk}(\mathbf{d}) = \frac{1}{|\mathcal{D}|} \int_{\mathcal{D}} \sigma_{uk}^2(\mathbf{u}; \mathbf{d}) d\mathbf{u}$ and $Q_{uk}^*(\mathbf{d}) = \max_{\mathbf{u} \in \mathcal{D}} \sigma_{uk}^2(\mathbf{u}; \mathbf{d})$ respectively. We can approximate both of these with a large but finite sample of target locations from \mathcal{D} or a large fixed grid in \mathcal{D} .

3.2. Parameter Uncertainty Kriging

Assuming that all covariance function parameters are known, the MSPE from kriging at an arbitrary location \mathbf{u} is $\sigma_{uk}^2(\mathbf{u})$. This underestimates the MSPE when those parameters must be estimated. An approximation of the correct MSPE, which we call the parameter uncertainty kriging variance (PUK variance), is given by (Zimmerman & Cressie, 1992; Abt, 1999)

$$E[Y(\mathbf{u}) - \hat{Y}_{uk}(\mathbf{u})]^2 \approx \sigma_{puk}^2(\mathbf{u}; \mathbf{d}, \hat{\boldsymbol{\theta}}) = \sigma_{uk}^2(\mathbf{u}; \mathbf{d}, \hat{\boldsymbol{\theta}}) + \text{tr}[\mathbf{A}(\mathbf{u}; \mathbf{d}, \hat{\boldsymbol{\theta}})\mathbf{I}^{-1}(\mathbf{d}, \hat{\boldsymbol{\theta}})]$$

where $\hat{\boldsymbol{\theta}}$ is the maximum likelihood estimate of $\boldsymbol{\theta}$ from previously observed data, \mathbf{I}^{-1} is the inverse Fisher information (FI) matrix, and $\mathbf{A} = \text{var}[\partial \hat{Y}_{uk} / \partial \boldsymbol{\theta}]$. The ij th element of the FI matrix can be derived as $\text{tr}\left(\mathbf{C}_Z^{-1} \frac{\partial \mathbf{C}_Z}{\partial \theta_i} \mathbf{C}_Z^{-1} \frac{\partial \mathbf{C}_Z}{\partial \theta_j}\right)$ while \mathbf{A} can be derived using elementary matrix calculus. From these we define the mean and maximum PUK variances as $\bar{Q}_{puk}(\mathbf{d}) = \frac{1}{N_t} \sum_i^{N_t} \sigma_{puk}^2(\mathbf{t}_i; \mathbf{d})$ and $Q_{puk}^*(\mathbf{d}) = \max_{i=1,2,\dots,N_t} \sigma_{puk}^2(\mathbf{t}_i; \mathbf{d})$ respectively.

3.3. Houston Ozone Monitoring

The Texas Commission on Environmental Quality (TCEQ) publishes a variety of environmental data for Texas, including many environmental indicators that directly relate to public health. We focus on ozone in the Houston-Galveston-Brazoria area. The TCEQ measures ozone at a network of monitoring locations in this area and publishes daily maximum eight-hour ozone concentrations (DM8s) in parts per billion (ppb) for each monitoring location. DM8s are computed as follows. First, the TCEQ creates publishes an hourly average (in ppb) for each monitoring location. Then an eight hour average is constructed at that location for each contiguous eight-hour period where all eight measurements were present for a given day. The maximum of these eight-hour averages for a given day is the published DM8. Days with less than 18 valid eight-hour averages have no published DM8.

In August 2016 there were 44 active monitoring locations in the Houston-Galveston-Brazoria area. For each location \mathbf{u} we compute the monthly average DM8, which we denote by $Z(\mathbf{u})$. At one location, MRM-3 Haden Road, there are two DM8 observations of 0 ppb in the month of August. We assume that these were data errors and omit them for the purposes of computing $Z(\mathbf{u})$ at that location. Of the 44 locations, one has 15 valid DM8 measurements of 31 possible valid measurements, another has 24 valid measurements, and the rest of the locations have at least 27 valid measurements.

The hypothetical design problem we consider is the addition of five new ozone monitoring locations to the Houston-Galveston-Brazoria monitoring network in Harris County, where Houston is located, with the goal of predicting ozone concentrations within Harris County. Of the 44 existing locations, 33 are already in Harris County, though the locations outside of the county are still useful for spatial prediction within Harris County.

Let $Z(\mathbf{u})$ denote the measured average DM8 as location \mathbf{u} and let $Y(\mathbf{u})$ denote the true DM8. We assume that $Z(\mathbf{u})$ is a noisy Gaussian measurement of $Y(\mathbf{u})$; i.e., the data model is $Z(\mathbf{u}) \sim N[Y(\mathbf{u}), \tau^2]$. The parameter τ^2 represents variability added due to both measurement error from the instruments and potentially sampling error from measuring DM8 on less than the full 31 days in August. At the process level, we assume that $Y(\mathbf{u})$ is a geostatistical process with mean function $\mu(\mathbf{u}) = \mathbf{x}(\mathbf{u})'\boldsymbol{\beta}$ and exponential covariance function $C(\mathbf{u}, \mathbf{v}) = \sigma^2 \exp(-\|\mathbf{u} - \mathbf{v}\|/\phi)$. We assume that any fine scale variability is measurement error and captured in the data model. We considered several possible mean functions: constant in \mathbf{u} , linear in \mathbf{u} , and quadratic in \mathbf{u} . We fit each model using maximum likelihood and found that quadratic terms were unnecessary, but linear terms did significantly help explain variation in $Y(\mathbf{u})$.

We use both PUK design criteria in order to choose the five new locations in Harris County: $\bar{Q}_{puk}(\mathbf{d})$ and $Q_{puk}^*(\mathbf{d})$, both defined in Section 3. We assume that the goal is the predict average DM8 in all of Harris County, so we approximate the continuous versions of $\bar{Q}_{puk}(\mathbf{d})$ and $Q_{puk}^*(\mathbf{d})$ with the finite sample versions using a grid of 1229 points, obtained by gridding up the smallest rectangle containing Harris County and throwing away all points outside of hte county. We try a variety of PSO algorithms in order to select the new locations. Since the design space only allows new monitoring locations within Harris County, we define $\bar{Q}_{uk}(\mathbf{d}) = Q_{uk}^*(\mathbf{d}) = \infty$ when any of the proposed locations are outside of Harris County. In theory the swarm can be forced to only propose locations inside of Harris County, but this a much simpler approach. Existing sampling locations outside of Harris County are still used in the estimation of the model and in the construction of the PUK variances.

[INSERT PSO RESULTS HERE... CURRENTLY RUNNING/PENDING TO BE RUN ON THE SERVER, THOUGH WE MAY WANT TO TWEAK IT - TAKES 2-3 DAYS TO RUN]
